ski et al. (1998) have shown that damage to putative AIP results in impairments of visually-guided grasping. In contrast to optic ataxia, ideomotor apraxia is a disorder that primarily affects planning of skilled actions, while leaving on-line control relatively unaffected. For example, these patients often have considerable difficulty pantomiming tool-use actions, yet have little or no difficulty reaching and grasping visually presented objects (for a comprehensive review see Heilman, 1997). Since the turn of the previous century, it has been known that ideomotor apraxia results almost exclusively from damage to, or disconnection of, the left cerebral hemisphere (Leiguarda & Marsden 2000). Recent analyses implicate both the IPL and SPL in this disorder. Lesion overlap is most frequent in areas within and adjacent to the left IPS, including SPL (BA 7) and IPL (BA 39 and 40), as well as interconnected regions of the middle frontal gyrus (GFm: Haaland et al. 2000). Corroborating evidence comes from several functional neuroimaging studies of healthy adults showing activation of these regions during overt or imagined tool use actions involving either hand (Choi et al. 2001; Johnson-Frey 2003; Moll et al. 2000). Together, these findings indicate that representations necessary for planning skilled movements involve a left-lateralized parieto-frontal system. Further, this cerebral asymmetry appears to be true regardless of one’s hand dominance (Johnson-Frey et al., submitted; Lunsberg et al. 1998; Rayner et al. 1999). This contrasts sharply with the apparent contralateral organization of parietal mechanisms involved in on-line control that are damaged in optic ataxia. These differences should serve as an important constraint on theories concerning the organization of action representations.

Glover is correct in asserting that the contrasting deficits of optic ataxia and ideomotor apraxia patients suggest that actions do not depend on a unitary representational system. However, the distinction is not between planning and control but, rather, between actions that are planned and controlled entirely on the basis of immediate perceptual information versus skills that additionally involve accessing stored memories (Johnson-Frey 2003; Johnson-Frey & Grafton 2003). As reviewed above, on-line manual actions are controlled by functionally specialized parieto-frontal circuits that include contralaterally organized regions belonging either to the SPL or the IPL. By contrast, in the vast majority of individuals, manual skills (e.g., tool-use) are represented in a left-lateralized parieto-frontal system. Of course, the actual implementation of a skilled action in the real world necessarily involves cooperation between these two systems.

In short, this position differs from Glover’s in at least two respects. First, planning takes place in both representational systems, but for different types of actions; that is, skills versus non-skills. Second, depending on nature of the movement(s) involved (e.g., reaching, grasping, saccades), control can be accomplished in the SPL and/or IPL.

Is there an independent planning system? Suggestions from a developmental perspective

Zsuzsa Káldy a and Ilona Kovács b

Abstract: Glover argues that separate representations underlie the planning and the control phase of actions, and he contrasts his model with Goodale and Milner’s perception/action model. Is this representation indeed an independent representation within a more general action system, or is it an epiphenomenon of the interaction between the perception/action systems of the Goodale–Milner model?

We contrast the Glover and the Goodale–Milner models in Figure 1. According to our understanding, one of the main differences between them is the way they conceptualize the representation that the motor program is based on. In the Goodale–Milner model (Goodale & Milner 1992), it is the “action” representation of the dorsal stream (Repr action); while in Glover’s model, it is a representation underlying the planning phase (Repr planning). The two models disagree about the potential effects of visual context on this representation. According to Glover’s model, context has a potentially large effect on Repr planning while in the Goodale–Milner theory it does not (or the effect can only be small). Glover also claims that Repr planning determines certain parameters of the motor program, such as lifting force, posture choice, movement time and grip acceleration, and these parameters can be strongly influenced by illusion effects (see Glover, sect. 2.6.1, para. 4). Not all motor program parameters are under the control of Repr planning – such as maximum grip aperture and pointing accuracy – are driven by Repr control, and these are the parameters that context-induced illusions do not influence.

We propose an experiment motivated by our recent developmental studies that could significantly contribute to this issue. We have studied four-year-old children’s and adults’ performance in a 2AFC version of the Ebbinghaus illusion (Titchener circles) task (Káldy & Kovács 2003; see also Kovács 2000). Both children and adults were asked to decide which one of the target circles amidst the context circles appeared larger. The task was entirely perceptual, that is, no action was required toward the target circles. Our results have shown that the magnitude of the illusion effect was significantly smaller in children than in adults, and our interpretation is that visual context integration is not fully developed in four-year-olds. In terms of the Goodale–Milner model, we found an age-dependent effect of the magnitude of the context-induced illusion on Repr perception. We proposed earlier that the ontogenetic development of the dorsal “action” system is faster than that of the ventral “perception” system in humans (Kovács 2000). Based on the age-dependent illusion effect on Repr perception and the faster maturation of the “action” system, we suggest an experiment that could decide about the independent existence of the “planning” system in Glover’s model. As Glover suggests, there are particular parameters of movement that seem to be affected by illusions because they are determined by Repr planning – Movement time as measured in the Ebbinghaus illusion is one of those parameters (van Donkelaar 1999). Taking into account the faster...
maturation of planning related areas, the Glover model would predict that children should demonstrate adult-like illusion effects in terms of movement time well before they do in the perceptual version of the Ebbinghaus illusion task. However, the Goodale–Milner model, in the strict sense, does not allow for illusion effects arising from the “action” system; therefore, the origin of the illusion should be in Repr$_{\text{perception}}$. In this case, young children should behave the same way as in the perceptual task: They should demonstrate much smaller illusions than adults. This test would be an interesting way to study the relationship between the two hypothetical concepts, Repr$_{\text{planning}}$ and Repr$_{\text{perception}}$, and the controversial period before the action starts.

### Action planning in humans and chimpanzees but not in monkeys

Nobuyuki Kawai

**Abstract:** Studies with primates in sequence production tasks reveal that chimpanzees make action plans before initiating responses and making online adjustments to spatially exchanged stimuli, whereas such planning isn’t evident in monkeys. Although planning may rely on phylogenetically newer regions in the inferior parietal lobe – along with the frontal lobes and basal ganglia – it dates back to as far as five million years ago.

Glover argues that planning is largely the province of a phylogenetically newer cortex in the inferior parietal lobe (IPL), and he suggests that “the role in the human IPL in action planning may have arisen quite recently in evolution and may be manifest in the uniquely human population lateralization in hand preference” (target article, sect. 1.2.1). Although planning is limited in macaque monkeys, as he suggests, a series of studies have revealed that chimpanzees, which are hominoids, are greatly skilled in action planning just as humans are.

Ohshima (1997) compared the reaction time of macaque monkeys and a chimpanzee in a sequence production task. Both species of primates were taught to select differently sized circles in a predetermined order. An analysis of the reaction times suggested that the monkeys identified only the first target to be selected in the task and only after (and/or during) the selection of that target – which resulted in its disappearance – would they search for the next target to be selected. This was because reaction times to subsequent targets decreased in a monotonic function. In contrast, a chimpanzee doing the same task spent the longest amount of time in selecting the first item of the sequence, followed by shorter reaction times for the remaining items.

Figure 1 (Kawai). The chimpanzee Ai performing the numerical ordering task in the “masking” trial (Kawai & Matsuzawa 2000b). The numerals were presented on the touch-sensitive monitor. Immediately after Ai had correctly chosen the lowest numeral (1), the remaining numerals were automatically masked. Ai continued to identify the numerals one by one in ascending order.

Figure 2 (Kawai). Reaction times selecting the first, second, third, fourth, and fifth items in the numerical ordering task with three different numerals (e.g., 1, 3, 7), the on-screen positions of the remaining two and 4%, respectively). In this and other similar studies (Kawai 2001; Kawai & Matsuzawa 2000a; 2000b; 2001a; 2001b), only the reaction time for the first numeral was longer than those for the remaining numerals, which did not differ (Fig. 2). These results indicate that she could memorize the correct sequence of any five numerals (Kawai & Matsuzawa 2000b).

The chimpanzee Ai also exhibits skillful on-line control of action. In the same numerical ordering task with three different numerals (e.g., 1, 3, 7), the on-screen positions of the remaining two...
